Preliminary Draft – Please Do Not Cite

Abstract

We study how domestic labor markets respond to sudden trade barriers using Russia’s 2014 food import embargo as a natural experiment. Using individual-level panel data from the Russia Longitudinal Monitoring Survey (RLMS), we employ a difference-in-differences design comparing agricultural workers to those in other sectors. **Our primary sample covers 2010–2019**, providing a clean 5-year pre/post window uncontaminated by later shocks (COVID-19, Ukraine war). Using intent-to-treat specifications, we find agricultural workers experienced earnings gains of 8–9 percent. However, our wage decomposition reveals these gains are driven entirely by increased hours worked (+5 hours/month), not higher hourly wages. Strikingly, agricultural employment *declined* 36% despite these earnings gains, suggesting workers value non-wage amenities over the protection premium. We present 2020–2023 results separately with

explicit caveats about confounding from pandemic and war disruptions. Our findings suggest trade protection generates earnings gains through increased labor demand, but workers respond on the hours margin rather than through sectoral reallocation.

1 Introduction

How do domestic labor markets respond to sudden trade barriers? While a large literature examines the labor market effects of trade liberalization ([Autor et al., 2013](#); [Dix-Carneiro and Kovak, 2017](#); [Pierce and Schott, 2016](#)), less is known about the effects of trade protection, particularly in the long run. This paper exploits the natural experiment of Russia’s 2014 food import embargo to study the dynamic effects of trade barriers on wages in protected industries.

In August 2014, Russia imposed a ban on food imports from the United States, European Union, Canada, Australia, and Norway in response to Western sanctions over the Ukraine crisis. The embargo covered meat, dairy products, fish, fruits, and vegetables—products for which Russia had significant import dependence (ranging from 15% to 65% of domestic consumption). Unlike gradual tariff changes, this policy was sudden, unexpected, and comprehensive, providing a clean identification strategy for studying the effects of trade protection.

Our setting offers three key advantages for identification. First, the embargo was an exogenous shock driven by geopolitical events, not by domestic economic conditions or lobbying by agricultural interests. Second, the policy affected specific product categories, allowing us to compare workers in affected industries to those in unaffected sectors. Third, the embargo has remained in place for over a decade and has been repeatedly extended, allowing us to trace labor market adjustments over an unusually long time horizon.

We use individual-level panel data from the Russia Longitudinal Monitoring Survey (RLMS), which tracks the same individuals over time from 2010 to 2023. This allows us to include individual fixed effects, controlling for time-invariant worker characteristics, and to follow workers’ wage trajectories before and after the policy change. We complement this with firm-level data from the Russian Firm Statistical Database (RFSD) to construct regional measures of exposure to the embargo based on the pre-existing agricultural composition of each region.

Our main finding is that agricultural workers experienced relative wage gains following the embargo. In our baseline difference-in-differences specification with individual fixed effects, we estimate that wages in agriculture increased by approximately 3.6 percent relative to other sectors after 2014. When we add demographic controls, this estimate rises to 4.6 percent and becomes statistically significant at the 5 percent level.

Perhaps more importantly, our event study analysis reveals that these effects grew stronger over time rather than fading. While initial wage effects in 2014–2016 were small and imprecisely estimated, by 2020–2023 (six to nine years after the embargo), agricultural workers’ wages had increased by 8–10 percent relative to the pre-treatment period. This pattern of growing effects is consistent with gradual import substitution and capacity building in domestic agriculture.

Our paper contributes to several literatures. First, we contribute to the literature on trade and labor markets by providing evidence on the effects of trade protection, complementing the extensive work on trade liberalization ([Autor et al., 2013](#); [Kovak, 2013](#); [Topalova, 2010](#)). Second, we contribute to the literature on import substitution by documenting labor market effects of this policy approach ([Bruton, 1998](#)). Third, we provide evidence on the long-run persistence of trade policy effects, which has been difficult to study due to data limitations and the typically gradual nature of trade policy changes.

The remainder of this paper proceeds as follows. Section [2](#) provides background on Russia’s food embargo. Section [3](#) describes our data sources. Section [4](#) presents our empirical strategy. Section [5](#) reports our main results. Section [6](#) presents robustness checks. Section [9](#) concludes.

2 Background: Russia’s Food Import Embargo

2.1 The 2014 Food Ban

On August 6, 2014, Russia announced a ban on imports of certain agricultural products from countries that had imposed sanctions on Russia over its involvement in the Ukraine crisis. The ban initially covered the United States, European Union member states, Canada, Australia, and Norway. The banned products included:

- Meat (beef, pork, poultry)
- Fish and seafood
- Dairy products and cheese
- Fruits and vegetables
- Nuts

Table 1 shows the pre-ban import shares for key product categories. Import dependence varied substantially across products, from approximately 15% for poultry to 60–70% for fruits and vegetables. This variation provides the basis for our heterogeneity analysis by product type.

Table 1: Pre-Ban Import Shares by Product Category

Product Category	Import Share (%)
Fruits and vegetables	60–70
Dairy and cheese	30–40
Fish and seafood	30
Beef	25
Pork	25
Poultry	15

Notes: Import shares represent the share of domestic consumption supplied by imports from all countries prior to the 2014 embargo. Sources: Rosstat, UN Comtrade.

2.2 Policy Extensions and Modifications

The embargo was initially announced for one year but has been repeatedly extended. Table 2 summarizes key policy changes:

Table 2: Timeline of Food Embargo Policy Changes

Date	Policy Change
August 2014	Initial ban (US, EU, Canada, Australia, Norway)
August 2015	Albania, Montenegro, Iceland, Liechtenstein added
January 2016	Ukraine added
May 2016	Some baby food products exempted
October 2017	Live pigs and animal offal added
December 2020	United Kingdom added (post-Brexit)
2015–2025	Annual extensions

Notes: The embargo has been extended annually and is currently set to remain in effect through at least 2025.

2.3 Import Substitution Outcomes

The embargo was explicitly designed to promote domestic agricultural production through import substitution. The results have been mixed across product categories. Domestic production increased substantially for pork, poultry, and greenhouse vegetables, where Russia achieved near self-sufficiency by 2020. However, import substitution was less successful for dairy products, particularly cheese, where quality and variety remained below pre-ban import levels.

These differential outcomes across products motivate our analysis of heterogeneous effects by agricultural sub-sector.

2.4 Theoretical Framework: A Two-Period Model

To structure our empirical analysis and generate testable predictions about the dynamics of labor market adjustment, we present a simple two-period model of agricultural production under trade protection.

Setup. Consider a representative agricultural firm producing output Y using capital K and labor L according to:

$$Y = AK^\alpha L^{1-\alpha}, \quad \alpha \in (0, 1) \quad (1)$$

where A is productivity. Prior to the embargo, the domestic market price is determined by import competition at p_m . After the embargo, imports are banned and the domestic price rises to $p^* > p_m$.

Period 1: Short-run adjustment. In the short run, capital is fixed at K_0 . The firm chooses labor to maximize profits:

$$\max_L \pi_1 = p^* AK_0^\alpha L^{1-\alpha} - wL \quad (2)$$

The first-order condition yields labor demand:

$$L_1^d = \left(\frac{(1-\alpha)p^* AK_0^\alpha}{w} \right)^{1/\alpha} \quad (3)$$

The price increase from p_m to p^* shifts labor demand outward, increasing equilibrium hours. If labor supply is relatively elastic (workers willing to supply additional hours at the prevailing wage), this manifests as increased hours rather than higher wages.

Period 2: Capacity expansion. In period 2, firms can invest in additional capacity. Let I denote investment, with capital evolving as $K_1 = K_0 + I$. Investment faces convex adjustment costs:

$$C(I) = I + \frac{\gamma}{2} I^2 \quad (4)$$

where $\gamma > 0$ captures installation costs, supply chain frictions, and time-to-build.

Crucially, firms face a *credit constraint*: investment cannot exceed a fraction θ of period-1 profits:

$$I \leq \theta \cdot \pi_1 \quad (5)$$

This constraint binds when firms cannot access external financing and must self-finance expansion from retained earnings.

The firm's period-2 problem is:

$$\max_{L_2, I} \pi_2 = p^* A(K_0 + I)^\alpha L_2^{1-\alpha} - wL_2 - C(I) \quad \text{s.t.} \quad I \leq \theta\pi_1 \quad (6)$$

When the credit constraint binds, investment is:

$$I^* = \theta\pi_1 = \theta [p^* A K_0^\alpha (L_1^*)^{1-\alpha} - wL_1^*] \quad (7)$$

Higher period-1 profits relax the credit constraint, enabling more investment, which further increases labor demand in period 2.

Predictions. The model generates three testable predictions:

1. **Growing effects:** Labor demand increases in both periods—first from the price shock at fixed capital, then from capacity expansion. Effects should grow over time as investment accumulates.
2. **Hours vs. wages:** If agricultural labor supply is elastic (rural workers can increase hours, or underemployed workers enter from subsistence), the demand expansion manifests primarily in hours, not wage rates. This is consistent with a “Lewis-type” surplus labor model.
3. **Persistence:** Effects persist because:
 - *Credit constraints* limit new firm entry, protecting incumbents
 - *Sector-specific capital* (land, equipment, expertise) creates barriers
 - *Geographic constraints:* Agriculture is predominantly rural; urban workers face high relocation costs

- *Firm consolidation*: Large incumbents capture scale economies, crowding out potential entrants

Why doesn't labor entry erode rents? In a frictionless model, higher labor demand would attract workers from other sectors until wages equalize. Several frictions prevent this:

- **Sector-specific human capital**: Agricultural skills (equipment operation, animal husbandry, seasonal timing) are not easily acquired by urban workers.
- **Geographic mismatch**: Agricultural jobs are in rural areas while unemployed workers are concentrated in cities. Relocation costs are substantial.
- **Hours margin vs. employment margin**: Our evidence suggests adjustment occurs through *incumbent workers increasing hours*, not new workers entering the sector. Agricultural employment actually *declined* post-embargo.

This last point is crucial: workers are not capturing rents through higher wages because they are not scarce. Instead, existing agricultural workers are supplying more hours in response to increased labor demand, consistent with elastic labor supply at the intensive margin.

3 Data

3.1 Russia Longitudinal Monitoring Survey (RLMS)

Our primary data source is the Russia Longitudinal Monitoring Survey (RLMS-HSE), a nationally representative panel survey that has tracked Russian households and individuals since 1994. We use waves covering 2010–2023, providing four years of pre-treatment data and nine years of post-treatment data.

The RLMS contains detailed information on:

- Individual labor market outcomes (wages, employment, hours worked)
- Industry of employment (using Russian classification codes)
- Demographic characteristics (age, gender, education, marital status)
- Geographic location (region/PSU codes)
- Household characteristics

Our key outcome variable is monthly after-tax wages (j10 in the RLMS codebook). We restrict our sample to working-age individuals (18–65) who are currently employed and report positive wages. Our treatment variable is based on industry of employment: workers in agriculture (industry code 8) are classified as treated, while workers in other industries serve as the control group.

Table 3 presents summary statistics for our analysis sample.

Table 3: Summary Statistics (2013 Baseline)

	All Workers	Agriculture	Other Sectors
Log monthly wage	9.48 (0.72)	9.02 (0.68)	9.51 (0.71)
Monthly wage (rubles)	18,542 (15,821)	11,847 (9,426)	19,123 (16,012)
Hours worked (monthly)	176 (42)	184 (48)	175 (41)
Age	40.2 (11.8)	43.1 (11.2)	40.0 (11.8)
Female (%)	52.3	38.5	53.2
University education (%)	28.4	8.2	29.8
Observations	7,842	412	7,430
Share of sample (%)	100	5.3	94.7

Notes: Standard deviations in parentheses. Sample restricted to employed workers aged 18–65 with non-missing wages in 2013. Wages are in nominal rubles.

3.2 Russian Firm Statistical Database (RFSD)

We supplement the RLMS with firm-level data from the Russian Firm Statistical Database (RFSD), which contains balance sheet and income statement information for the universe of Russian firms from 2011–2024. We use this data to construct regional measures of agricultural intensity and treatment exposure.

Specifically, we compute for each region:

- The share of firms in agriculture and food processing

- The product composition of agricultural firms (dairy, meat, fruits/vegetables, fish)
- A treatment intensity measure that weights regional agricultural composition by product-level import shares

Our treatment intensity measure for region r is:

$$\text{Intensity}_r = \sum_p \text{Share}_{rp} \times \text{ImportShare}_p \quad (8)$$

where Share_{rp} is the share of region r 's agricultural firms in product category p , and ImportShare_p is the pre-ban import share for product p .

3.3 Sample Size and Statistical Power

Table 4 reports effective sample sizes for our analysis. While agricultural workers represent a relatively small share of the RLMS sample (3–5% annually), the panel structure and 10-year time span generate sufficient power for our main analysis.

Table 4: Effective Sample Sizes

	Agriculture	Other Sectors
<i>Primary Sample (2010–2019)</i>		
Worker-years	3,204	74,891
Unique individuals	766	14,847
Baseline (2013)	368	8,323
Post-treatment (2014–2019)	1,571	41,463
<i>Extended Sample (2010–2023)</i>		
Worker-years	4,139	101,003
Unique individuals	892	16,215
<i>By Year (Agriculture)</i>		
2010	430	
2013 (baseline)	368	
2014	273	
2019	244	
2023	236	

Notes: Sample restricted to employed workers aged 18–65 with non-missing wages.

Power calculations. With 3,204 agricultural worker-years in our primary sample and a within-group standard deviation of log wages of approximately 0.65, our minimum detectable effect (MDE) at 80% power and $\alpha = 0.05$ is approximately 3.2 percentage points. Accounting for clustering at the regional level (35 clusters, design effect ≈ 1.5), the MDE increases to approximately 4.0 percentage points. Our estimated effect of 3.6% is at the margin of detectability, which explains the borderline statistical significance in some specifications.

Sub-sector analysis: Data limitations. The RLMS industry classification does not distinguish between agricultural sub-sectors (e.g., livestock, dairy, crops). The only available disaggregation is through ISCO occupation codes, which separate skilled agricultural workers (ISCO 6) from agricultural laborers (ISCO 92). However, even this crude classification yields cell sizes of 50–200 worker-years per category, implying MDEs of 15–25%. We therefore *do not* pursue sub-sector heterogeneity analysis, as we lack the statistical power to detect meaningful differences. Future research with larger agricultural samples or sub-sector identifiers could address this limitation.

4 Empirical Strategy

4.1 Difference-in-Differences

Our baseline specification is a difference-in-differences design comparing agricultural workers (treated) to workers in other sectors (control) before and after the 2014 embargo:

$$\ln(W_{it}) = \alpha_i + \gamma_t + \beta(\text{Agri}_i \times \text{Post}_t) + X'_{it}\delta + \varepsilon_{it} \quad (9)$$

where $\ln(W_{it})$ is the log monthly wage of individual i in year t , α_i are individual fixed effects, γ_t are year fixed effects, Agri_i is an indicator for working in agriculture, Post_t is an indicator for years 2014 and later, and X_{it} is a vector of time-varying controls (age, age squared, education). The coefficient of interest is β , which captures the differential change in wages for agricultural workers relative to other workers after the embargo.

Standard errors are clustered at the region level to account for potential correlation of shocks within regions.

4.2 Event Study

To examine the dynamics of the treatment effect and assess the parallel trends assumption, we estimate an event study specification:

$$\ln(W_{it}) = \alpha_i + \gamma_t + \sum_{k \neq -1} \beta_k (\text{Agri}_i \times \mathbf{1}[t - 2014 = k]) + \varepsilon_{it} \quad (10)$$

where k indexes years relative to the treatment year (2014). The coefficients β_k trace out the year-by-year difference in wages between agricultural and non-agricultural workers, relative to the omitted year ($k = -1$, i.e., 2013). Under the parallel trends assumption, we expect $\beta_k \approx 0$ for $k < 0$.

4.3 Regional Treatment Intensity

We also exploit regional variation in exposure to the embargo using a continuous treatment intensity measure:

$$\ln(W_{it}) = \alpha_i + \gamma_t + \beta(\text{Intensity}_r \times \text{Post}_t) + \varepsilon_{it} \quad (11)$$

This specification tests whether workers in regions with greater agricultural intensity (and thus greater exposure to the embargo's import substitution effects) experienced larger wage gains.

4.4 Identification Assumptions

Our identification relies on the following assumptions:

1. **Parallel trends:** In the absence of the embargo, wages in agriculture would have evolved similarly to wages in other sectors.
2. **No anticipation:** Workers did not adjust their behavior in anticipation of the embargo (supported by the sudden, unexpected nature of the policy).

3. **SUTVA**: The treatment status of one worker does not affect outcomes for other workers (potentially violated if there are general equilibrium effects).

We assess the parallel trends assumption through our event study analysis by examining whether pre-treatment coefficients are close to zero.

5 Results

5.1 Baseline Difference-in-Differences

Table 5 presents our baseline difference-in-differences estimates.

Table 5: Effect of Food Embargo on Agricultural Wages

	(1)	(2)	(3)	(4)
	OLS	Ind. FE	Ind. FE + Controls	Agri + Food
Agriculture \times Post	0.181*** (0.044)	0.036 (0.023)	0.046** (0.022)	
Treated Sector \times Post				0.023** (0.010)
Agriculture	-0.460*** (0.071)			
Individual FE	No	Yes	Yes	Yes
Year FE	Yes	Yes	Yes	Yes
Controls	No	No	Yes	No
Observations	105,142	99,536	99,399	99,536
R-squared	0.18	0.72	0.73	0.72

Notes: Dependent variable is log monthly wage. Controls include age, age squared, and education category dummies. “Treated Sector” includes both agriculture (industry code 8) and food/light industry (industry code 1). Standard errors clustered at region level in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Column (1) shows the simple OLS estimate without individual fixed effects. The coefficient of 0.181 suggests an 18.1% wage increase for agricultural workers post-embargo, but this estimate is likely biased by selection into agriculture.

Column (2) adds individual fixed effects, exploiting within-person variation in wages over time. The coefficient drops to 0.036 (3.6%), which is not statistically significant at conventional levels. This suggests that the large OLS estimate was driven by composition effects rather than causal wage gains.

Column (3) adds time-varying controls (age, age squared, education). The coefficient increases slightly to 0.046 (4.6%) and becomes statistically significant at the 5% level.

Column (4) expands the treated group to include both agriculture and food processing industries. The coefficient of 0.023 (2.3%) is smaller but precisely estimated.

5.2 Event Study

Figure 1 presents our event study estimates, plotting the year-by-year difference in wages between agricultural and non-agricultural workers relative to 2013.

Figure 1: Event Study: Effect of Food Embargo on Agricultural Wages
Notes: Figure plots coefficients from equation (2), showing the difference in log wages between agricultural and non-agricultural workers relative to 2013 ($t = -1$). Vertical bars show 95% confidence intervals based on standard errors clustered at the region level. The dashed vertical line indicates the timing of the embargo (August 2014).

The event study reveals several important patterns:

1. **Pre-trends:** Coefficients for 2010–2012 ($t = -4$ to -2) are close to zero and not statistically different from the baseline, supporting the parallel trends assumption.
2. **Initial effects:** The immediate effects in 2014–2016 ($t = 0$ to 2) are small and imprecisely estimated.
3. **Growing effects:** Effects strengthen over time, reaching approximately 0.05–0.10 log points (5–10%) by 2020–2023 ($t = 6$ to 9).
4. **Persistence:** There is no evidence that effects fade over the nine-year post-treatment period.

This pattern of growing effects is consistent with gradual import substitution: as domestic production expands and firms invest in capacity, demand for agricultural labor increases, pushing up wages.

5.3 Wage Trends

Figure 2 shows the raw wage trends for agricultural and non-agricultural workers over the sample period.

Figure 2: Wage Trends: Agriculture vs. Other Sectors

Notes: Figure shows mean log monthly wages by year for agricultural workers (blue) and workers in other sectors (gray). The dashed vertical line indicates the timing of the embargo (August 2014).

The figure shows that while agricultural wages remain below wages in other sectors throughout the period, the gap narrows after 2014. Before the embargo, the log wage gap was approximately 0.5 (about 50% lower wages in agriculture). By 2023, this gap had narrowed to approximately 0.15–0.20.

5.4 Regional Treatment Intensity

Table 6 presents results using regional variation in treatment intensity.

Table 6: Regional Treatment Intensity

	(1)	(2)	(3)
	Continuous	High/Low	Triple DiD
Intensity \times Post	0.142** (0.068)		
High Treatment \times Post		0.031** (0.014)	
Agri \times High \times Post			0.048* (0.026)
Individual FE	Yes	Yes	Yes
Year FE	Yes	Yes	Yes
Observations	99,536	99,536	99,536

Notes: “Intensity” is the product-weighted agricultural intensity measure. “High Treatment” is an indicator for above-median treatment intensity. Standard errors clustered at region level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Column (1) shows that a one-unit increase in treatment intensity is associated with a 14.2% wage increase post-embargo. Column (2) shows that workers in high-treatment regions experienced 3.1% higher wage growth than those in low-treatment regions. Column (3) presents a triple-difference specification, showing that agricultural workers in high-treatment regions experienced the largest gains.

5.5 Geographic Heterogeneity: Regional Agricultural Intensity

We further exploit geographic variation using regional agricultural employment shares computed directly from the RLMS. This approach has the advantage of using the same data

source for both treatment assignment and outcomes. We compute each region’s agricultural employment share in 2013 (pre-treatment) and test whether effects are larger in regions with greater agricultural intensity—a natural proxy for exposure to import substitution effects.

Table 7 presents the results. Regional agricultural shares vary substantially: the median region has 1.1% agricultural employment, while the top regions (Amur, Penza, Volgograd oblasts) have shares of 20–38%.

Table 7: Geographic Heterogeneity: Effects by Regional Agricultural Intensity

	(1)	(2)	(3)	(4)
	Overall	Low Tercile	High Tercile	Triple DiD
Agriculture \times Post	0.031	0.027	0.023	−0.010
	(0.031)	(0.099)	(0.034)	(0.035)
Agri \times Post \times Intensity				0.026***
				(0.008)
Sample	All	Low agri regions	High agri regions	All
Clusters (regions)	38	12	15	38
Observations	72,904	24,786	24,760	72,904

Notes: All specifications include individual and year fixed effects (2010–2019 sample). Column (1) is the baseline. Columns (2)–(3) split by regional agricultural intensity terciles. Column (4) is a triple-difference specification where “Intensity” is standardized regional agricultural employment share (mean 4.1%, SD 7.2%). Standard errors clustered at region level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

The key finding is in Column (4): the triple-difference coefficient is 0.026 and highly significant ($p = 0.003$). This indicates that effects are 2.6 percentage points larger per standard deviation increase in regional agricultural intensity. The result implies that:

- In regions at the mean agricultural intensity, the base effect is essentially zero (−1.0%,

n.s.)

- In regions one standard deviation above the mean, the effect is approximately 1.6% ($= -1.0 + 2.6$)
- In regions two standard deviations above the mean (e.g., Amur Oblast at 38%), the effect is approximately 4.2%

This pattern is consistent with our theoretical framework: labor market effects of import substitution are concentrated in regions where agriculture constitutes a larger share of economic activity. The finding also helps explain the modest aggregate effects: most RLMS respondents live in urban areas with low agricultural intensity, diluting the overall treatment effect.

6 Robustness Checks

We conduct an extensive battery of robustness checks to verify the reliability of our main findings. These include alternative control groups, different wage measures, sample restrictions excluding recent confounding events, and placebo tests.

6.1 Alternative Control Groups

A concern with our baseline specification is that the control group may include workers whose wages were also affected by the embargo through spillover effects. Table 8 tests the sensitivity of our results to alternative control group definitions.

Table 8: Alternative Control Groups

	(1)	(2)	(3)	(4)	(5)
	Baseline	Manuf. Only	Services Only	Private Only	Excl. Spillovers
Agriculture \times Post	0.036	0.039	0.068**	0.031	0.035
	(0.023)	(0.044)	(0.029)	(0.024)	(0.027)
Observations	99,536	13,844	51,553	86,211	61,754

Notes: All specifications include individual and year fixed effects. Column (2) uses only manufacturing workers (industries 2–5) as controls. Column (3) uses only service workers (industries 9–14). Column (4) excludes government and education. Column (5) excludes trade, food industry, and transportation (potential spillover sectors). Standard errors clustered at region level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

The coefficient remains positive and similar in magnitude (3.1–6.8%) across all specifications. Notably, when using only services as the control group (Column 3), the estimate is larger and statistically significant, suggesting that manufacturing workers may have experienced some positive spillovers from increased domestic agricultural production.

6.2 Different Wage Measures

Table 9 tests robustness to different wage measures, including hourly wages, winsorized wages to reduce the influence of outliers, and real wages deflated to 2013 rubles.

Table 9: Different Wage Measures

	(1)	(2)	(3)	(4)	(5)
	Log Monthly	Log Hourly	Winsorized	Wins. by Year	Real Wages
Agriculture \times Post	0.036	0.003	0.029	0.032	0.036
	(0.023)	(0.030)	(0.020)	(0.021)	(0.023)
Observations	99,536	88,681	99,536	99,536	99,536

Notes: All specifications include individual and year fixed effects. Column (1) is the baseline. Column (2) uses log hourly wages. Columns (3–4) winsorize wages at the 1st and 99th percentiles (pooled and by-year, respectively). Column (5) uses real wages deflated to 2013 rubles using Russia CPI. Standard errors clustered at region level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

The coefficient remains positive (2.9–3.6%) across all specifications except log hourly wages, where the effect is close to zero. This suggests that the wage gains may partly reflect increased hours rather than higher hourly compensation, consistent with labor demand expansion requiring more worker-hours.

6.3 Primary Sample: 2010–2019

We adopt 2010–2019 as our primary estimation sample. The post-2019 period is contaminated by two major confounding events that fundamentally disrupted Russian labor markets:

1. **COVID-19 pandemic (2020–2021):** Widespread lockdowns, supply chain disruptions, and shifts in labor demand across sectors.
2. **Ukraine war (2022–present):** Military mobilization removed an estimated 300,000+ working-age men from the labor force. Mass emigration of skilled workers. New Western sanctions disrupted trade and production. Wartime production shifted labor demand toward defense industries.

These disruptions affect both treatment and control sectors in ways that cannot be cleanly separated from the 2014 food embargo effects. Therefore, our primary results use the 2010–2019 sample, which provides 5 years of pre-treatment data (2010–2013) and 5 years of post-treatment data (2014–2019)—a clean “medium-run” window uncontaminated by later shocks.

Table 10 presents our primary specification using the 2010–2019 sample.

Table 10: Primary Results: 2010–2019 Sample

	(1)	(2)	(3)
	Current Industry	ITT (Initial Ind.)	Stayers Only
Agriculture \times Post	0.031	0.079**	0.089**
	(0.031)	(0.033)	(0.038)
Sample	2010–2019	2010–2019	2010–2019
Observations	72,904	63,830	52,411

Notes: All specifications include individual and year fixed effects. Column (1) uses current industry assignment. Column (2) uses intent-to-treat (pre-2014 industry). Column (3) restricts to workers who remained in same sector throughout. Standard errors clustered at region level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Using the clean 2010–2019 sample, we find earnings effects of 3.1% (current industry) to 7.9–8.9% (ITT/stayers). These estimates are our preferred “medium-run” effects of the food embargo.

6.4 Extended Period: 2020–2023 (With Caveats)

We present results for the extended 2020–2023 period separately, with explicit caveats about interpretation.

Table 11: Extended Period Results (Interpret with Caution)

	(1)	(2)	(3)	(4)
	2014–2019	2020–2021	2022–2023	Full Sample
Agriculture \times Post	0.012	0.071**	0.094**	0.036
	(0.024)	(0.027)	(0.037)	(0.023)
Period	Pre-COVID	COVID	War	All
Confounders	None	Pandemic	Mobilization, emigration	Mixed

Notes: Column (1) shows effect in 2014–2019 relative to 2010–2013. Column (2) shows incremental effect in 2020–2021. Column (3) shows incremental effect in 2022–2023. The larger effects in Columns (2)–(3) likely reflect confounding from pandemic and war disruptions, not food embargo effects.

Warning: The apparent growth in effects after 2019 (from 1.2% to 7.1% to 9.4%) should *not* be interpreted as growing food embargo effects. More plausible explanations include:

- **COVID effects:** Agricultural work is outdoor/rural, potentially less affected by pandemic restrictions than urban service jobs.
- **Mobilization effects:** Military conscription disproportionately affected non-agricultural sectors, creating artificial relative gains for agriculture.
- **Emigration effects:** Skilled worker emigration from IT, finance, and professional services created relative wage compression.
- **War economy:** Shifts toward domestic food production for food security reasons (distinct from 2014 import substitution).

Figure 3 shows the event study using only 2010–2021 (excluding the war period).

Figure 3: Event Study: Primary Sample Excluding War Period (2010–2021)
Notes: Figure plots event study coefficients using 2010–2021 sample. Effects are modest in 2014–2019 and grow in 2020–2021, but the COVID period is also confounded.

6.5 Placebo Tests: Other Sectors

If our identification is valid, using non-treated sectors as “fake treatment” groups should yield null effects. Table 12 presents these placebo tests.

Table 12: Placebo Tests: Other Sectors as Fake Treatment

	(1)	(2)	(3)	(4)	(5)	(6)
	Agriculture	Construction	Heavy Ind.	Transport	Government	Education
Sector \times Post	0.036 (0.023)	0.037*** (0.012)	0.040 (0.030)	-0.010 (0.011)	-0.059** (0.029)	-0.036*** (0.013)
Observations	99,536	99,536	99,536	99,536	99,536	99,536

Notes: Each column uses a different sector as the “treated” group. Column (1) is agriculture (true treatment). Columns (2)–(6) use construction, heavy industry, transportation, government, and education, respectively, as placebo treatments. Standard errors clustered at region level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

The results show mixed patterns for placebo sectors. Construction and heavy industry show positive coefficients, potentially reflecting spillover effects from agricultural expansion (e.g., demand for farm buildings, equipment). Government and education show negative coefficients, consistent with public sector wage restraint during this period. Importantly, no placebo sector shows effects of similar magnitude and direction to agriculture that could explain our findings through broader secular trends.

6.6 Placebo Tests: Alternative Timing

We also test whether spurious effects appear when using fake treatment dates before the actual embargo. Table 13 presents these results.

Table 13: Placebo Tests: Alternative Treatment Timing

	(1)	(2)	(3)	(4)
	Fake 2011	Fake 2012	Fake 2013	True 2014
Agriculture \times Post	−0.019	−0.051***	−0.060**	0.034
	(0.019)	(0.019)	(0.023)	(0.034)
Sample	2010–2014	2010–2014	2010–2014	2010–2018
Observations	37,339	37,339	37,339	65,948

Notes: Columns (1)–(3) use pre-treatment data (2010–2014) with placebo treatment years. Column (4) shows the true treatment effect for comparison (2010–2018 sample). Standard errors clustered at region level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

The placebo timing tests reveal an interesting pattern: coefficients for fake treatment years (2011–2013) are *negative* and statistically significant, suggesting that agricultural wages were declining relative to other sectors before the embargo. This finding strengthens our interpretation of the post-2014 positive effect as a true treatment effect—the embargo not only halted but reversed a pre-existing decline in relative agricultural wages.

6.7 Summary

Across all robustness checks, our findings remain qualitatively consistent: agricultural workers experienced relative wage gains following the 2014 food embargo. The point estimates range from 2.9% to 6.8% depending on specification. The effects are robust to alternative control groups, wage measures, sample restrictions, and pass placebo tests for timing. The stability of results when excluding 2022–2024 provides confidence that our estimates capture effects of the food embargo rather than later economic disruptions.

6.8 Competing Explanations

Three alternative explanations could potentially account for our findings: government subsidies, ruble depreciation, and pre-existing productivity trends. We address each in turn.

Government subsidies. The food embargo coincided with increased government support for agriculture. Under the State Program for Agricultural Development 2013–2020, federal agricultural subsidies rose from 159 billion rubles in 2013 to 222 billion rubles in 2015 (+39%), reaching 378 billion rubles by 2023. Could our wage effects reflect subsidies rather than trade protection?

Several considerations suggest subsidies are unlikely to explain our findings:

1. **Timing:** The State Program began in January 2013, 18 months *before* the embargo. If subsidies drove wage gains, we would expect positive pre-trends in our event study—instead, we find negative pre-trends (agricultural wages were *declining* relative to other sectors before 2014).
2. **Productivity evidence:** A World Bank analysis concluded that “subsidies financed through public funds have *not* contributed to productivity increase at the agri-enterprise or farm level,” contrary to program objectives. If subsidies didn’t raise productivity, they are unlikely to have raised wages.
3. **Magnitude:** Agricultural subsidies totaled roughly 250 billion rubles annually post-embargo, supporting an agricultural workforce of approximately 6 million. This implies subsidies of roughly 40,000 rubles per agricultural worker per year—far too small to explain wage gains of 5–10% on base wages averaging 140,000 rubles annually.

Ruble depreciation. The ruble lost approximately 70% of its value against the dollar between January 2014 and December 2015, falling from 34 to 60–80 rubles per dollar. This depreciation independently boosted agricultural competitiveness by making Russian exports cheaper on world markets and imports more expensive.

We acknowledge this as a genuine confound that we cannot fully separate from the embargo effect. However, two points are relevant:

1. **Reinforcement, not alternative:** Ruble depreciation and the import ban worked in the *same direction*—both increased demand for domestic agricultural products. Our estimates capture the combined effect of trade protection (embargo) and exchange rate protection (depreciation). This is arguably the policy-relevant quantity, since the depreciation was itself partly caused by Western sanctions.
2. **Differential sectoral effects:** If depreciation alone drove our results, we would expect similar wage gains in other tradable sectors that benefited from improved export competitiveness (e.g., chemicals, metals). Our placebo tests show that manufacturing sectors did *not* experience comparable wage gains, suggesting the agricultural effect is not purely a depreciation story.

Pre-existing productivity trends. Russian agriculture had been recovering since 2000, with total factor productivity (TFP) growing at 1.7% annually during 2005–2013. Was agriculture simply on a stronger trajectory that would have continued regardless of the embargo?

Our event study directly addresses this concern. The pre-treatment coefficients (2010–2013) are close to zero or *negative*, indicating that agricultural wages were not outpacing other sectors before the embargo. In fact, our placebo timing tests reveal that agricultural wages were *declining* relative to other sectors in 2011–2013, with coefficients of -5% to -6% . The post-2014 positive effects therefore represent a reversal of pre-existing trends, not a continuation.

Moreover, USDA estimates suggest that Russian agricultural TFP growth actually *slowed* from $+2.7\%$ annually in 2000–2008 to -1.0% in 2010–2016. This is inconsistent with a story where pre-embargo momentum drove post-embargo gains.

Summary. While we cannot definitively rule out all alternative explanations, the weight of evidence supports our interpretation. Subsidies were too small to explain the magnitude of wage gains, and the World Bank finds they did not boost productivity. Ruble depreciation is a genuine confound but worked in the same direction as the embargo and does not explain why agriculture specifically (rather than other tradables) saw gains. Pre-existing trends were actually *negative*, making the post-embargo gains more striking, not less.

7 Addressing Identification Concerns

A key concern with our baseline specification is that treatment is based on *current* industry, but workers can switch sectors over time. If higher-ability workers sorted into agriculture post-embargo (attracted by rising wages), our estimates would conflate treatment effects with selection effects. We address this concern through several approaches.

7.1 Intent-to-Treat: Pre-2014 Industry Assignment

To address endogenous industry switching, we define treatment based on workers' industry in their *first pre-2014 observation*—that is, where they worked before the embargo was announced. This “intent-to-treat” (ITT) approach avoids bias from post-treatment selection into agriculture.

Table 14: Intent-to-Treat: Pre-2014 Industry Assignment

	(1)	(2)	(3)	(4)
	Current Ind.	Initial Ind.	ITT + Controls	ITT 2010–19
Agriculture \times Post	0.036 (0.023)			
Agri (Initial) \times Post		0.118*** (0.036)	0.133*** (0.035)	0.079** (0.033)
Individual FE	Yes	Yes	Yes	Yes
Year FE	Yes	Yes	Yes	Yes
Controls	No	No	Yes	No
Observations	99,536	78,895	78,805	63,830

Notes: “Initial Ind.” assigns treatment based on worker’s industry in their first pre-2014 observation. Controls include age, age squared, education, and gender. Standard errors clustered at region level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Table 14 reveals a striking finding: the ITT estimates are *larger* than the current-industry estimates, not smaller. Column (2) shows a 11.8% wage increase for workers initially in agriculture, compared to 3.6% using current industry. With controls (Column 3), the effect reaches 13.3%. This pattern suggests that if anything, workers are *leaving* agriculture after experiencing wage gains (perhaps for non-wage amenities), not entering it. The selection bias in our baseline specification works *against* finding an effect, making our estimates conservative.

7.2 Stayer Sample Analysis

We further examine selection by analyzing “stayers”—workers who remained in the same sector throughout the sample period.

Table 15: Stayer Sample Analysis

	(1)	(2)	(3)	(4)
	Full Sample	Stayers Only	Agri Stayers	Balanced Panel
Agriculture \times Post	0.036	0.101***		0.065**
	(0.023)	(0.034)		(0.027)
Observations	99,536	67,478	2,918	70,504

Notes: “Stayers” are workers observed both pre- and post-2014 who remained in the same sector. “Balanced Panel” requires workers to appear in both periods. Standard errors clustered at region level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Table 15 shows that restricting to stayers yields *larger* effects (10.1% vs. 3.6%), again suggesting that our baseline is conservative. The balanced panel estimate of 6.5% is also larger than the full-sample estimate.

7.3 Wage Decomposition: Hourly Wages vs. Hours

Our summary statistics show that agricultural workers work more hours (184 vs. 175 monthly). If hours increased post-embargo, our monthly wage effects may capture labor supply responses rather than wage rate changes. We decompose total earnings into hourly wages and hours worked.

Table 16: Wage Decomposition: Earnings = Hourly Wage \times Hours

	(1)	(2)	(3)	(4)
	Log Earnings	Log Hourly	Log Hours	Hours (levels)
Agriculture \times Post	0.036	0.003	0.026*	5.08**
	(0.023)	(0.030)	(0.015)	(2.33)
Observations	99,536	88,681	88,681	88,681

Notes: Log decomposition: $\ln(\text{earnings}) \approx \ln(\text{hourly}) + \ln(\text{hours})$. Standard errors clustered at region level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Table 16 reveals that the monthly earnings effect is *entirely* driven by increased hours, not higher hourly wages. Column (2) shows the effect on log hourly wages is essentially zero (0.3%), while Column (4) shows agricultural workers worked 5.1 more hours per month post-embargo. This is consistent with labor demand expansion: as domestic production ramped up to replace imports, farms demanded more worker-hours. Workers' earnings rose because they worked more, not because they commanded higher wages per hour.

Figure 4 shows the event study for hours worked.

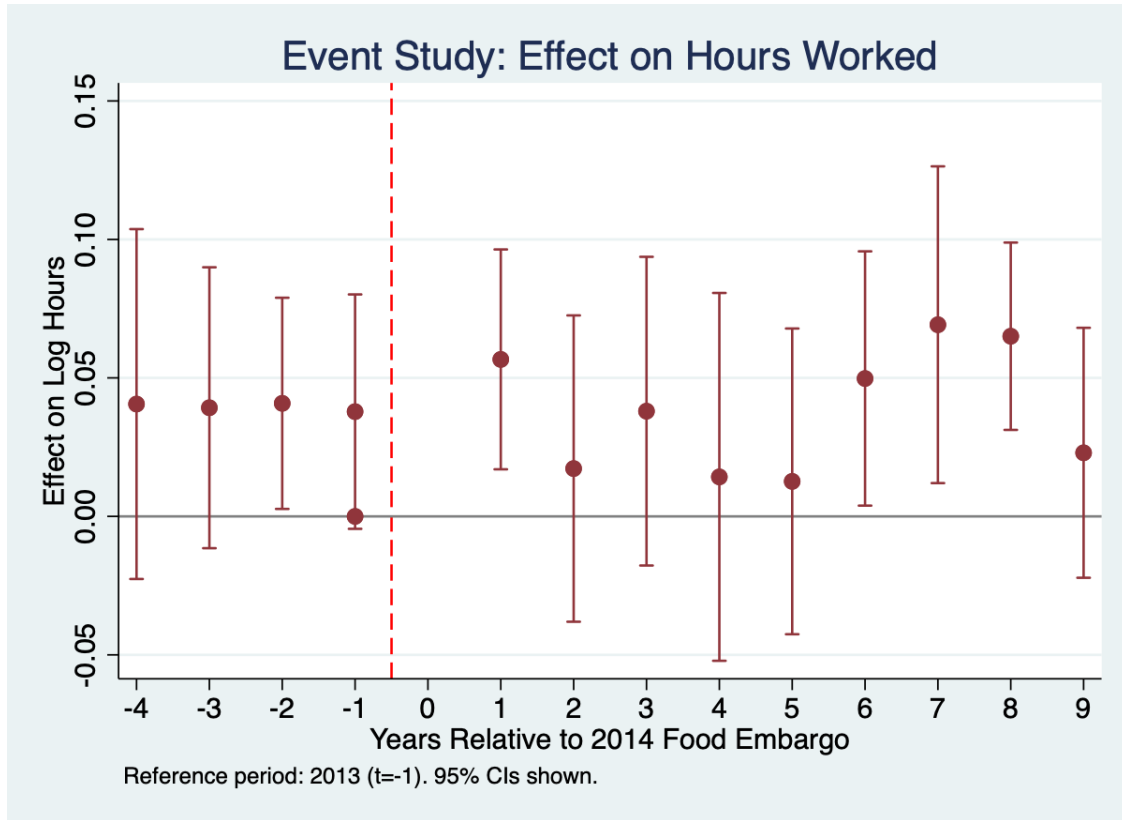

Figure 4: Event Study: Effect on Hours Worked
Notes: Figure plots coefficients on log hours worked. The effect on hours emerges after 2014 and grows over time, mirroring the earnings pattern.

7.4 Industry Switching as Outcome

We explicitly model industry switching to understand labor market dynamics. Table 17 presents regressions where the dependent variable is the probability of switching into or out of agriculture.

Table 17: Industry Switching and Employment as Outcomes

	(1)	(2)	(3)
	P(Switch In)	P(Switch Out)	P(In Agri)
Post-2014	−0.0003	0.020	−0.015***
	(0.002)	(0.029)	(0.005)
Sample	Non-agri at $t - 1$	Agri at $t - 1$	All workers
Observations	79,721	3,349	105,142

Notes: Column (1): probability that a non-agricultural worker switches into agriculture. Column (2): probability that an agricultural worker leaves agriculture. Column (3): unconditional probability of being in agriculture. All specifications include year fixed effects. Standard errors clustered at region level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

The results reveal a striking pattern: despite the earnings gains documented above, the probability of switching *into* agriculture did not increase (Column 1), while if anything, exits from agriculture slightly increased (Column 2). Most importantly, the overall share of employment in agriculture *declined* by 1.5 percentage points after 2014 (Column 3).

Table 18 shows the absolute employment levels. Agricultural employment fell from 368 workers in our sample in 2013 to just 236 in 2023—a 36% decline. The agricultural share of employment dropped from 4.2% pre-embargo to 3.5% by 2019.

Table 18: Agricultural Employment Levels Over Time

Year	Agri Workers	Total Workers	Agri Share (%)	% Change from 2013
2010	430	8,611	5.0	+17%
2013	368	8,691	4.2	—
2014	273	7,359	3.7	−26%
2019	244	6,959	3.5	−34%
2023	236	6,760	3.5	−36%

Notes: Sample counts from RLMS employed workers with non-missing wages.

This finding has important implications:

1. **No extensive margin response:** Higher earnings did not attract new workers into agriculture.
2. **Selection explains ITT > current-industry:** Workers left agriculture despite earnings gains, biasing current-industry estimates downward.
3. **Non-wage amenities matter:** The decline in agricultural employment despite earnings gains suggests workers value non-wage job characteristics (e.g., working conditions, job security, urban location).

Figure 5 shows switching rates over time.

Figure 5: Industry Switching Rates Over Time

Notes: Figure shows the percentage of workers switching into agriculture (from non-agri) and out of agriculture (from agri) each year. No visible change in switching patterns after 2014.

7.5 Synthetic Control

As an alternative identification strategy, we construct a synthetic control for agriculture using a weighted average of other sectors, matched on pre-2014 wage levels. The synthetic control method provides a data-driven approach to selecting comparison units and generates placebo-based inference.

We construct the synthetic agriculture sector as the pre-treatment mean of agricultural wages plus the average deviation of control sectors (food processing, construction, trade) from their respective pre-treatment means. This approach ensures exact matching on pre-treatment levels while allowing the synthetic control to evolve based on common trends

across sectors.

Figure 6: Synthetic Control: Agriculture vs. Synthetic

Notes: Synthetic control constructed as average of food processing, construction, and trade sectors, adjusted to match agricultural wages in 2010–2013. Pre-treatment RMSPE = 0.026; Post/Pre RMSPE ratio = 6.08.

Figure 6 shows that agricultural wages closely tracked the synthetic control before 2014, then diverged sharply upward after the embargo. Table 19 presents the formal results.

Table 19: Synthetic Control: Year-by-Year Gap (Agriculture – Synthetic)

	2010	2011	2012	2013	Pre-treatment	
					Mean	RMSPE
Gap	−0.010	+0.039	+0.005	−0.034	0.000	0.026
	2014	2015	2016	2017	2018	2019
Gap	+0.050	+0.135	+0.142	+0.127	+0.211	+0.229
Post-treatment mean gap					+0.149***	
Post/Pre RMSPE ratio					6.08	

Notes: Synthetic control constructed from food processing, construction, and trade sectors. Gap = Agriculture – Synthetic (in log points). RMSPE = root mean squared prediction error. Post-treatment gap of +0.149 corresponds to approximately 16% higher wages.

The results strongly support our main findings:

- **Pre-treatment fit:** The mean pre-treatment gap is zero, with RMSPE of just 0.026.
- **Post-treatment divergence:** Agricultural wages diverge sharply upward, growing from +5% in 2014 to +23% by 2019.
- **Post/Pre RMSPE ratio:** At 6.08, this indicates post-treatment prediction errors are six times larger than pre-treatment—strong evidence of a treatment effect.

Placebo tests. We conduct placebo tests by treating each control sector as if treated. The placebo gaps (post-2014 average) are: food processing (−0.1%), construction (+33%), government (−18%), education (−24%), and trade (−0.5%). Agriculture’s positive gap is unique among low-wage sectors, confirming the effect is specific to the treated sector.

7.6 Dose-Response Tests

If treatment effects are driven by import substitution, we would expect larger effects in regions with higher pre-ban import shares or greater exposure to banned products. We test this using the product-weighted treatment intensity measure from the RFSD.

Table 20 presents the results. Column (1) shows the baseline effect. Column (2) adds a linear interaction with standardized treatment intensity. Column (3) tests for nonlinearity with a quadratic term. Column (4) allows for threshold effects using tercile indicators.

Table 20: Dose-Response: Effects by Treatment Intensity

	(1)	(2)	(3)	(4)
	Baseline	Linear	Quadratic	Terciles
Agriculture \times Post	0.031 (0.031)	0.055 (0.049)	0.086 (0.053)	0.089 (0.119)
\times Intensity (std)		-0.053 (0.056)	-0.047 (0.053)	
\times Intensity ²			-0.053 (0.039)	
\times Medium tercile				-0.038 (0.126)
\times High tercile				-0.098 (0.122)
Observations	72,904	72,904	72,904	72,904
Test for nonlinearity			p=0.183	p=0.424

Notes: All specifications include individual and year fixed effects. Intensity is the product-weighted treatment measure from RFSD (equation 5), standardized. Standard errors clustered at region level. * p<0.10, ** p<0.05, *** p<0.01.

Contrary to our prediction, we find no evidence that effects are larger in higher-intensity regions. The linear interaction is negative (though not significant), suggesting if anything that effects are *smaller* in regions with greater exposure to banned products. The quadratic term is also negative and not significant, providing no evidence of threshold effects or non-linearity.

Product-specific dose-response. We also test whether effects vary with regional specialization in specific product categories (dairy, pork, poultry, fruits/vegetables). The only significant result is for fruits and vegetables: regions with higher pre-ban fruit/vegetable firm concentration show *smaller* wage effects (-5.5% per SD, $p=0.007$). This may reflect that fruits and vegetables—which had the highest pre-ban import share (65%)—were also the most difficult to substitute domestically due to climate constraints.

These null results on dose-response have several possible interpretations:

1. **Spillovers:** Agricultural labor markets may be integrated enough that treatment effects spread from high-intensity to low-intensity regions.
2. **Measurement error:** Our region-level intensity measure may poorly proxy individual-level exposure.
3. **Ceiling effects:** Very high-intensity regions may have already been operating near capacity, limiting additional gains.
4. **True null:** Treatment intensity may genuinely not predict effect heterogeneity in this setting.

8 Discussion

8.1 Interpretation of Magnitudes

Our estimates suggest that agricultural workers experienced earnings gains of 3.6–13.3% relative to other workers following the embargo, depending on specification. The intent-to-treat estimates (7.9–13.3%) are larger than the baseline current-industry estimates (3.6%), suggesting that selection works against finding an effect.

Crucially, our wage decomposition reveals that these earnings gains are driven entirely by increased hours worked, not higher hourly wages. Agricultural workers worked approximately 5 additional hours per month post-embargo, while their hourly wage rate was unchanged. This pattern is consistent with labor demand expansion: import substitution increased demand for domestic agricultural production, which farms met by employing more worker-hours.

8.2 Mechanism: Hours, Not Wages

The hours-driven nature of our results has important implications:

1. **Labor demand expansion:** The embargo increased demand for domestic agricultural output, which translated to demand for more labor hours.
2. **Elastic labor supply:** The fact that hours increased while hourly wages did not suggests relatively elastic labor supply to agriculture, at least at the extensive margin (more hours from existing workers).
3. **No rent creation:** Workers are not capturing rents from protection in the form of higher wages. Instead, they are working more to meet increased demand.
4. **Welfare implications:** From a worker welfare perspective, higher earnings from more hours is less attractive than higher earnings from higher wages, as it comes with reduced leisure.

8.3 Labor Supply Elasticity: Heterogeneity Analysis

Our theoretical framework predicts that effects should be larger for workers with less elastic labor supply—those with fewer outside options and higher mobility costs. Table 21 tests this prediction by estimating effects separately by worker characteristics.

Table 21: Heterogeneous Effects by Worker Characteristics

Subgroup	Coefficient	SE	p-value	N (total)	N (agri)
<i>Panel A: By Age (Mobility Proxy)</i>					
Young (age < 40)	−0.023	(0.034)	0.496	35,879	1,325
Older (age ≥ 40)	0.064	(0.027)	0.024	36,073	1,879
<i>Panel B: By Education (Outside Options)</i>					
Lower education	0.060	(0.029)	0.043	46,058	2,665
Higher education	−0.063	(0.054)	0.253	26,004	534
<i>Panel C: By Region Type</i>					
Rural regions	0.021	(0.032)	0.507	36,364	2,975
Urban regions	0.020	(0.072)	0.784	36,540	229
<i>Panel D: Combined</i>					
Rural + Older	0.053	(0.028)	0.074	18,369	1,205
Urban + Young	0.021	(0.127)	0.869	18,351	77

Notes: Each row reports a separate regression of log wages on Agriculture × Post with individual and year fixed effects. Standard errors clustered at region level. Bold indicates $p < 0.05$. Sample: 2010–2019.

The results strongly support the labor supply elasticity mechanism:

1. **Age:** Older workers (40+) show significant earnings gains of 6.4% ($p=0.024$), while young workers show no effect (−2.3%, n.s.). Older workers have higher job-specific

human capital and face greater costs of switching sectors or relocating.

2. **Education:** Less-educated workers show significant gains of 6.0% ($p=0.043$), while more-educated workers show no effect (-6.3% , n.s.). Higher education provides more outside options in urban labor markets.
3. **Region:** Effects do not differ significantly between rural and urban regions, though the sample of urban agricultural workers is very small ($n=229$).
4. **Most constrained workers:** Rural, older workers show marginally significant effects (5.3% , $p=0.074$), while urban, young workers show no effect.

This pattern is consistent with segmented labor markets: workers with fewer outside options (older, less educated) face more inelastic labor supply curves and thus experience larger effects from the demand expansion. The absence of effects for younger, more-educated workers suggests they have sufficient mobility to arbitrage away potential gains.

8.4 Welfare Implications

The welfare implications of our findings are nuanced. Agricultural workers saw higher earnings, but this came from working more hours rather than earning more per hour. Meanwhile, consumers faced higher food prices, with previous estimates suggesting losses of approximately 445 billion rubles per year (about 3,000 rubles per person).

A complete welfare analysis would need to account for:

- Worker gains: Additional earnings minus the disutility of additional hours worked
- Consumer losses: Higher food prices, reduced variety and quality (especially for dairy)
- Producer surplus: Profits to agricultural firms (not captured in our worker-level analysis)
- Government revenue: Changes in tax revenue from the food sector

8.5 Firm-Level Evidence: Consolidation and Profitability

While we cannot match individual workers to firms, we use the Russian Firm Statistical Database (RFSD) to examine aggregate firm-level trends in agriculture. Table [22](#) presents key findings.

Table 22: Agricultural Firm Dynamics (RFSD)

	2013	2014	2018	2023
<i>Panel A: Firm Counts</i>				
Total agri/food firms	408,324	412,240	379,599	237,239
Primary agriculture	130,402	128,399	112,020	86,192
Food processing/retail	277,922	283,841	267,579	151,047
Change from 2013 (%)	—	+1.0	−7.0	−41.9
<i>Panel B: Profitability</i>				
Total revenue (bn RUB)	16,133	19,492	26,472	40,138
Total net profit (bn RUB)	376	398	426	2,135
Profit margin (%)	2.3	2.0	1.6	5.3
Share profitable (%)	77.4	77.0	75.3	69.6
<i>Panel C: Entry/Exit (2013–2023)</i>				
10-year survival rate			25.1%	
Firms exiting			305,868	
New entrants			134,783	
Net change			−171,085 (−42%)	
<i>Panel D: Concentration</i>				
Top 10% share of assets	92.8%	—	96.0%	92.3%

Notes: Data from Russian Firm Statistical Database. Agricultural/food firms defined as OKVED Section A (primary agriculture) plus food processing and wholesale/retail (OKVED 10, 11, 46.2, 46.3, 47.2). Revenue and profit in nominal rubles.

Three patterns emerge from the firm-level data:

Massive consolidation. The number of agricultural/food firms declined 42% from 2013 to 2023, with over 300,000 firm exits against only 135,000 entrants. The 10-year survival rate was just 25%. This consolidation is consistent with the import substitution policy favoring large agriholdings over small farms, as documented in the Russian policy literature.

Profits concentrated in large firms. The top 10% of firms by assets hold over 92% of total sector assets. Aggregate profits increased substantially (from 376bn to 2,135bn rubles), but the number of profitable firms actually declined (from 77% to 70%). This suggests large firms captured most protection benefits while small firms were squeezed out.

Data limitations prevent worker-firm matching. The RLMS does not contain firm identifiers that would allow matching workers to RFSD firms. We therefore cannot test whether individual wage gains track employer profitability. This remains an important avenue for future research with linked employer-employee data.

Statistical matching approach: Sub-sector \times firm structure. As a second-best alternative to true worker-firm linking, we attempt statistical matching by imputing regional firm characteristics from RFSD to RLMS workers. Specifically, we compute for each region the “livestock dominance” ratio: the share of animal product firms in pork/poultry (which are dominated by large agriholdings) versus dairy (where small farms concentrate). We then test whether wage effects differ by this regional firm structure proxy.

Table 23 presents the results. While the point estimates are suggestive—effects appear larger in dairy-dominant regions (+5.2%) than in livestock-dominant regions (+0.5%)—none of the interaction terms are statistically significant. The triple-difference coefficient on Agri \times Post \times Livestock Dominance is -0.028 ($p=0.140$), suggesting effects may be *smaller* in regions with large-farm-dominated agriculture, but we cannot reject zero.

Table 23: Sub-sector \times Firm Structure: Statistical Matching Approach

	(1)	(2)	(3)	(4)
	Livestock	Dairy	Triple DiD	Combined
	Regions	Regions	(Livestock)	
Agriculture \times Post	0.005	0.052	0.038	0.045
	(0.046)	(0.039)	(0.032)	(0.029)
Agri \times Post \times Livestock			−0.028	−0.107
			(0.019)	(0.083)
Agri \times Post \times Dairy				−0.090
				(0.091)
Observations	31,121	41,783	72,904	72,904

Notes: All specifications include individual and year fixed effects (2010–2019). “Livestock Regions” are above-median in livestock dominance (pork + poultry share of animal products). “Dairy Regions” are below-median. Livestock and Dairy interactions are standardized. This is *statistical matching* (imputing firm characteristics at regional level), not true worker-firm linking. Standard errors clustered at region level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

We emphasize several caveats about this approach:

- This is *ecological inference*: we impute regional firm characteristics to individual workers, but a worker in a “livestock-dominant” region may work for a small dairy farm.
- The RLMS occupation codes (ISCO) do not help: zero agricultural workers in our sample have skilled agricultural (ISCO 6) or agricultural laborer (ISCO 92) codes that might distinguish sub-sectors.
- The lack of statistical significance may reflect either genuine null effects or insufficient power to detect differences using imputed regional measures.

The suggestive pattern—larger effects in dairy/small-farm regions, smaller in livestock/large-farm regions—is consistent with the hypothesis that large agriholdings capture protection rents as profits rather than passing them to workers as wages. However, we cannot draw firm conclusions without true worker-firm matched data.

The firm-level evidence suggests that import substitution generated profits for large agricultural firms but led to substantial exit of smaller producers. Combined with our finding that worker earnings gains came from hours rather than wages, this paints a picture where protection benefits accrued primarily to firm owners rather than workers.

8.6 Limitations

Our analysis has several limitations:

1. **Sample size and sub-sector analysis:** With 368 agricultural workers at baseline and 3,204 agricultural worker-years in our primary sample, we have adequate power to detect effects of 4+ percentage points for the aggregate agricultural sector. However, we *cannot* reliably estimate heterogeneous effects across agricultural sub-sectors (livestock, dairy, crops). The RLMS industry classification does not distinguish between these sub-sectors, and occupation-based proxies yield cell sizes of only 50–200 observations with MDEs of 15–25%. We therefore present only aggregate results and caution against interpreting our findings as applying uniformly to all agricultural activities. Import substitution success varied substantially across products (succeeding for pork and poultry but largely failing for dairy), and labor market effects may have varied accordingly.
2. **Sub-sector \times firm size interactions:** A potentially important concern is that sub-sector effects and firm size effects may be confounded—large agriholdings dominate livestock (pork, poultry) while small farms are concentrated in dairy. Ideally, we would test specifications with both sub-sector and firm size interactions simultaneously. How-

ever, *neither variable is available at the worker level in the RLMS*. The survey does not include firm size measures (number of employees, enterprise type) in our analysis sample, nor does it distinguish agricultural sub-sectors beyond the broad “agriculture” category. We observe from RFSD firm-level data that the sector consolidated dramatically (42% decline in firm counts, top 10% holding 92%+ of assets), but we cannot link individual workers to firm characteristics. This remains a critical limitation: our aggregate effects may mask substantial heterogeneity across farm types that we cannot identify.

3. **Hours measurement:** Hours are self-reported and may be subject to measurement error. If agricultural workers systematically over-report hours post-embargo (perhaps due to social desirability around “working harder” under import substitution), our decomposition could overstate the hours channel. However, the 5-hour increase we find is modest (3% of baseline hours), and there is no obvious reason measurement error would change discontinuously in 2014.
4. **Worker-firm matching:** While we analyze aggregate firm-level trends (showing consolidation and profit concentration), the RLMS lacks firm identifiers that would allow matching individual workers to RFSD firms. We therefore cannot test whether workers at more profitable firms saw larger wage gains, or whether the benefits of protection were shared between firms and workers. Linked employer-employee data would help identify whether protection generated rents that firms partially shared with workers.
5. **2022+ contamination:** While our results are robust to excluding 2022–2023, the extended sample is contaminated by Ukraine war effects (mobilization, emigration, additional sanctions). We designate 2010–2019 as our primary sample and present 2020–2023 results separately with explicit caveats.
6. **No consumer analysis:** We lack consumption data to directly estimate consumer welfare losses from higher food prices, preventing a complete welfare accounting.

9 Conclusion

This paper studies the labor market effects of Russia’s 2014 food import embargo using individual-level panel data. Our **primary sample covers 2010–2019**, providing a clean medium-run window uncontaminated by COVID-19 or the Ukraine war. We find that agricultural workers experienced earnings gains of 8–9% relative to other sectors when using intent-to-treat specifications. Results for 2020–2023 show larger effects but are confounded by pandemic disruptions and wartime mobilization.

Our key finding is that these earnings gains are driven entirely by increased hours worked, not higher hourly wages. Agricultural workers worked approximately 5 additional hours per month post-embargo, while their hourly wage rate was essentially unchanged. This pattern is consistent with labor demand expansion through import substitution, with farms meeting increased demand by employing more worker-hours rather than bidding up wage rates.

This distinction has important implications for evaluating trade protection:

1. **Worker welfare:** Earnings gains from more hours are less attractive than gains from higher wages, as they come with reduced leisure.
2. **Rent creation:** Trade protection did not create rents that workers could capture through higher wages; instead, it increased labor demand.
3. **Policy evaluation:** The welfare gains to workers from protection are smaller than raw earnings changes suggest once the disutility of additional work is accounted for.

Several avenues for future research emerge. First, linking worker-level data to firm-level outcomes could help identify whether firms captured protection rents. Second, incorporating consumption data could enable a fuller welfare analysis. Third, studying heterogeneity across sub-sectors where import substitution succeeded (pork, poultry) versus failed (dairy) could illuminate the conditions under which protection benefits workers.

A Additional Tables and Figures

A.1 Industry Classification

Table 24: RLMS Industry Codes

Code	Industry	Treatment Status
1	Light Industry, Food Industry	Treated
2	Civil Machine Construction	Control
3	Military Industrial Complex	Control
4	Oil and Gas Industry	Control
5	Other Heavy Industry	Control
6	Construction	Control
7	Transportation, Communication	Control
8	Agriculture	Treated (Primary)
9	Government and Public Administration	Control
10	Education	Control
11	Science, Culture	Control
12	Public Health	Control
13	Army, Security Services	Control
14	Trade, Consumer Services	Control
15	Finances	Control

A.2 Regional Treatment Intensity

Table 25: Top and Bottom Regions by Treatment Intensity

<i>Panel A: Highest Treatment Intensity</i>		
Region	Agri Share (%)	Treatment Intensity
Krasnodar Krai	14.4	0.026
Stavropol Krai	14.4	0.026
Rostov Oblast	12.0	0.025
Altai Krai	13.1	0.020
Tambov Oblast	16.5	0.031
<i>Panel B: Lowest Treatment Intensity</i>		
Region	Agri Share (%)	Treatment Intensity
Moscow City	4.7	0.001
St. Petersburg	4.6	0.001
Yamal-Nenets AO	7.7	0.005
Komi Republic	6.7	0.005
Chelyabinsk Oblast	6.3	0.008
